

Carbon Capture and Storage Power Stations

Carbon capture and storage refers to a process of capturing carbon dioxide from and storing it in suitable sites, from which it will not enter into atmosphere. This can provide solutions to reduce carbon emissions from fossil fuel based power plants. This lever provides choices to the users, for selecting different level of carbon capture and storage linked power plants. Impact of user's choices on various outputs like emission reduction and cost implications can be seen.

Level 2

Level 2 assumes that power plants with CCS usage will be deployed at slow rate. This could be because costs are high and are a barrier to deployment. CCS usage will start in 2030 and will reach 500 MW in 2050.

Level 1

Level 1 assumes that no plants with CCS will be commissioned, which might be because of high upfront cost and government's focus on increasing electricity generation from renewable energy sources.

Level 3

Level 3 assumes that CCS based plants will increase at a much faster rate. This could be because of owing national commitments on GHG reductions and state government effort. Cumulative capacity of plants with CCS technology will reach 2.4 GW.

Level 4

Level 4 which is the most optimistic scenario, assumes that growth rate of plants with CCS technology will be much higher, which could be because of decrease in capital cost and technological advancements. Cumulative installed capacity of CCS based plants increases to 6 GW by 2050.
